Q: Linear regulator fails with non-zero supply voltage I'm working on a project that will need a small amount of current in a tight loop. For some of the more esoteric technologies I'm using PWM, but for the more common parts (5v digital logic, 12v 12A 5kVA AC motor controller) I have decided to use a linear regulator in place of any switching. Most of the theory of linear regulators I've read about uses a constant output voltage and a constant current source to control it, but I need to vary output current (and voltage) based on supplied power. With that in mind, I designed a circuit with an LM7805 (a very cheap regulator) and am running into an odd problem. With the supply voltage set at a constant 5v, the regulator works fine and the output current tracks the input voltage as expected. However, if I add a resistor into the circuit in series with the regulator's ground, the output current is essentially unusable. The output drops to about 1.2v and the speed of drop-off is extremely non-linear. Once the output voltage drops to 0.8v, the speed of drop-off is completely non-linear. The situation is much worse than that, even when the input supply voltage is set above that of the output, the output voltage drops off more quickly than the voltage drop at the input. I have used just about every textbook I can find, and have tested a similar circuit built from discrete parts on a breadboard
